Preventing frac hits and well interferences with fast marching simulation using embedded discrete fracture models constrained by poroelastic geomechanical modelling of enhanced permeability

A., Ouenes^{1,2*}, A., Bachir^{1,2}, R. Smaoui¹, C. Hammerquist¹, M. Paryani¹ present a practical application of Embedded Discrete Fracture Models in a Fast-Marching Simulator where poroelastic geomechanical simulation provides the necessary enhanced permeability of the fractures that cause frac hits and well interferences.

Introduction

Investors are not happy. A recent article by a major newspaper (Olson et al., 2019) again highlighted the issue of ‘underperforming’ unconventional wells’ production targets. It notes that financial executives from the oil industry state that predicting well performance is an art rather than a science. Others involved in the management of billions of shale assets offer their opinion by noticing that ‘Geology doesn’t line up with Excel spreadsheets too well, unfortunately.’ These sentiments reflect the perceived state of unconventional technology which is reduced to ‘an art and relying on Excel spreadsheets’. Such comments have dramatic consequences on all stakeholders in the unconventional business. A serious consequence came about shortly after the newspaper article was published: a law firm started an investigation targeting executives of an oil company accused of misleading their investors by providing them with false well performance forecasts. Lawyers and financiers quarreling about such highly technical matters put the burden on scientists and engineers to bring practical solutions to this complex problem. During this decade, great efforts have been made to better understand the performance of unconventional wells, but the challenges are overwhelming, and they evolve as our understanding of hydraulic fracturing progresses. Chief among these challenges, we find the issue of frac hits and well interferences.

Frac hits are not a novelty and engineers started trying to understand and model these issues years ago (Lawal et al., 2013; Guindon, 2015; Ouenes et al., 2017; Paryani et al., 2017; Vargas-Silva et al., 2018). Now that these well interferences are affecting the bottom line and Permian shale players see a reduction of 30% to 50% in their child and/or parent well productions (Xu et al., 2019), even plenary sessions in conferences are devoted to this topic (Jacobs, 2019). These gatherings provide a good opportunity to reiterate the need for acquiring data to help improve our understanding of the stated problems while recognizing the need for an interdisciplinary approach to develop solutions (Jacobs, 2019). Unfortunately, the first boom in development of unconventional reservoirs created these myths that are increasingly hard to dislodge

from the minds of many stakeholders who convinced themselves that we do not need to collect data, or model earth heterogeneities to improve our engineering designs, that there is a magical number of wells per section, and that it is OK to exchange debt among private equity-backed shale players who buy and sell billions of dollars of shale assets using decline curve analysis (DCA) and type curves. Unfortunately, the tools commonly used by the industry to design their hydraulic fracturing were invented in the 1980s and 1990s and lack the basic components needed to model and optimize the well spacing and hydraulic fracturing of the unconventional wells that will reduce or avoid the impact of frac hits and well interferences. New tools and technologies are needed to form the basis of the practical implementation of new science in unconventional reservoir development.

The science of unconventional

To properly model the behaviour of unconventional wells one needs to capture the first order physics that have a major impact on the well performance. This must account for geologic factors such as rock mechanical property variation, reservoir pressures, natural fractures and weak interfaces and their impact on the stress field which controls the resulting fracture geometry. To capture all these multi-disciplinary components, we have built a software platform able to provide the necessary tools needed for any unconventional problem using a single grid in a single project. As a result, we created a preventative workflow deployable at field-development time scales to reduce frac-hit risk and optimize well interference potential. To address the unconventional production modeling challenges, the requirement of multidisciplinary tools and rapid execution of the workflow is critical. A typical industry workflow to study an interference problem in a pad is an R&D project that could last 3 to 6 months and use tools that frequently lack the right physics or do not accurately represent geologic reality. These inadequate tools perpetuate the idea that the unconventional business is an art and will keep engineers using only spreadsheets because nobody has time for a three-month study to understand a

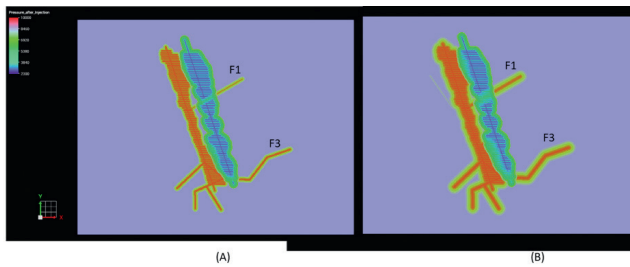

Figure 6 (A) Pressure around child and parent wells estimated using FMM and EDFM at the end of the hydraulic fracture injection period when using a constant fault permeability. Notice the higher pressure in green along F1 and F3 and inside the parent pressure field indicating the frac hit (B) pressure estimated using FMM and EDFM at the end of the hydraulic fracture injection period when using a variable and higher fault permeability derived from the strain simulation shown in Figure 4.

ask then what preventative measures can be taken to avoid this strong interference?

Jacobs (2018) described the latest ‘active well defence’ approaches where water is injected in parent wells to reduce the effect of the depletion when fracking the child well. The idea is proven to be effective in multiple basins but again the devil is in the detail and the presence of geologic discontinuities could greatly reduce the efficiency of this strategy. Figure 7 shows the pressure distribution after the parent well was pressurized first then followed by child injection. It appears that the presence of the faults could be a problem. Thus, the need to carefully design these water injection defences to avoid injecting in faults which could create the opposite effect and harm the child injection rather than help it.

These designs require data and rapid workflows able to provide quick answers. The use of surface drilling data provides the necessary information needed to capture the geologic and geomechanical variability at each well. The workflow described in this study is extremely fast and allows any engineer to employ the science of unconventional and develop predictive models even for issues involving complex physics such as frac hits and well interferences which cannot be predicted with Excel spreadsheets.

Conclusions

The introduction of the EDFM in a FMM simulator allows the rapid quantification of frac hits and well interferences. The use of validated reservoir geomechanics allows the estimation of the fracture and fault permeability required by the EDFM. The results derived from this new approach match field observations. The workflow also allows the examination of preventive measures involving water injection and their impact on the fracking of a child well. This entire analysis could be carried out on any well and can be completed in a timeframe counted in hours or days not weeks or months.
